## 1 Abstract

New Zealand has been working towards elimination of endemic (domestic) measles virus transmission, but has suffered from small, but significant outbreaks of measles after measles introductions from abroad. In this interim report we reviewed the draft *Progress Towards Measles Elimination in New Zealand - Final* report from the New Zealand Ministry of Health to the World Health Organization (WHO) Western Pacific Region. We identified additional analyses that may help understand risk of infection in New Zealand, began analyses of the cost of the current 2013-2014 outbreak and began modeling measles outbreaks to understand how they may be controlled and the possibility that measles may become endemic. Our key findings were:

- The *Progress Towards Measles Elimination in New Zealand - Final* report was of high quality and contained substantial information and useful analyses.
- New Zealand is at risk of frequent measles importation due to travel and endemic measles elsewhere in the globe.
- The cost of the current 2013-2014 measles outbreak is estimated to be at least \$ $\frac{3}{4}$  million.

- Analyses of outbreak data suggest that measles basic reproductive number ( $R_v$ , the number of secondary infections) values often include 1 and this year, 2014, is well above one. This analyses suggest improved vaccination is a requisite to prevent measles becoming endemic again.

## 2 Background

As a member of the World Health Organization (WHO) Western Pacific Region, New Zealand is committed to work towards measles elimination, defined as the interruption of endemic (domestic) measles virus transmission, as achieved in the Americas in 2002. The Western Pacific Region is expected to be the second WHO region to achieve measles elimination and it was announced that in March 2014 that Australia, Macao, Mongolia and the Republic of Korea have achieved measles elimination.

The last widespread measles outbreaks in New Zealand occurred in 1991 and in 1997. Since then, smaller but significant outbreaks have occurred in 2009 (mainly in Canterbury) and in 2011-2012 (mainly in Auckland region) and another significant outbreak is currently ongoing in the Auckland and Waikato regions. The outbreak in 2011-2012 lasted for more than 12 months and the current 2013-2014 outbreak started at the end of December 2013 (as on July 3, 2014). In 2013, prior to the 2013-2014 outbreak, New Zealand was advised by the Western Pacific Regional Verification Commission for Measles Elimination (RVC) it can request verification of non-endemic status three years after the last case of the 2011-12 outbreak in June 2012.

Previous analyses of measles, including two in New Zealand by Prof. Roberts (INSERT REFS), have estimated that the interruption of measles virus transmission can be achieved by herd immunity when approximately 95 percent of the population is homogeneously immune to measles. Thus, while New Zealand immunisation activities have led to measles outbreaks becoming less frequent, with decreasing numbers of cases, outbreaks still occur (as described above). Current overall population immunity estimates suggest that approximately 85 to 90 percent of the population is immune to measles, thus the reasons for the ongoing outbreaks are perhaps likely due to overall population immunity being less than 95 percent and there being pockets of susceptible, non-immune population remaining. Since 2009, all the outbreaks in New Zealand were linked to infections acquired (imported) from overseas, though previous work suggests these outbreaks still largely affect school-aged children and children under two years of age. Under two year olds are thought to be consistently among the most affected age groups because the first of two doses of measles, mumps and rubella vaccine (MMR) is not due until fifteen months.

### 3 Risk analysis review

A measles risk assessment has been started by the Ministry of Health to better assess current and future population immunity and high risk groups. Given the current measles outbreak, measles control is a priority for the Ministry and resources are available to control this outbreak and decrease the risk of future outbreaks.

- In this section we review the confidential report to the Western Pacific Regional Verification Commission for Measles Elimination risk assessment provided by the Ministry, titled *Progress Towards Measles Elimination in New Zealand - Final*.

Overall, we thought the review was very thorough. The report included substantial background information on measles immunisation in New Zealand (*Section 1.3*), the epidemiology of measles in New Zealand (*Section 2*), the quality of epidemiological surveillance and laboratory testing for measles (*Section 3*), and the levels of population immunity against the virus (*Section 4*). Additional details are included for many aspects of measles epidemiology and control, not least regarding the recent MMR coverage rates by birth cohort in New Zealand (*Section 4.2*) and the sustainability of the national immunisation programme (*Section 5*).

Within the report there are many tables and figures which give considerable detail on the measles situation in New Zealand. Overall these were of high quality, reporting both absolute measles case numbers and rates per 100,000 population in New Zealand.

Specific epidemiological details were provided for the 2011-2012 outbreak including *Figure 4*, the number and classification of measles notifications in New Zealand by month and year (2011 and 2012), with additional breakdown by age group in both years (*Figure 5*) and per 100,000 population (*Figures 6-8*). Similar presentation of the case data are provided for ethnicity (*Figures 9-10*) and New Zealand Index of Deprivation (NZDep) (*Figures 11-13*). Three figures, *Figures 12, 13, and 28*, show that there is spatial clustering of cases.

The report concludes that New Zealand's surveillance system has been performing well and that the Ministry is confident that measles has not been circulating since June 2012 and has not become endemic in NZ. We agree with the statement that measles did not become endemic and provide some preliminary analyses on the outbreaks since endemic measles elimination (see section X) that gives information regarding the likelihood of measles persisting within the population and becoming endemic, including important analysis of the current outbreak.

We agree with the report conclusions that testing for measles is performed appropriately within the required timeframe. Clearly improving inter-laboratory communication and collaboration and timeliness of the testing and reporting is necessary for rapid responses to measles introductions following measles control. Vaccination coverage presented in the report and to ourselves confirms that immunisation levels are approaching 94% for MMR dose one (birth cohorts 2009

Figure 1: Measles incidence from 1997 to 2014

and 2010) and 89% for MMR dose two (birth cohorts 2006 and 2007). However, only Asian and Pacific ethnicities have consistently had MMR dose one coverage approaching or over 95% levels for cohorts from 2007 onwards, and thus we agree with the report’s conclusions that timeliness and coverage of vaccination need improving. This is particularly in light of our preliminary modeling and risk analyses results (sections X and Y).

The analyses we believe could further inform the understanding of risk from measles infection are:

- Multivariate modelling to account for confounding within the univariate analyses.
- Inclusion of multivariate model results with local level immunity data to develop a risk map for New Zealand.
- Analyses of changing risk factors through time during outbreaks.
- Modelling transmission chains in the population to understand effective reproduction number.
- Development of risk maps to understand measles importation.

### 3.1 Additional risk analyses

In this section we provide a brief description of the work we are performing that we believe will help inform the Ministry of Health regarding the understanding of risk from measles. These analyses are intended to build on the analyses already included in the *Progress Towards Measles Elimination in New Zealand - Final* report reviewed above.

In light of the apparent increasing trend in measles incidence in the last few years Figure 1, we reviewed the information on measles importation and the origins of the introductions of measles into New Zealand. To help understand

Yemen	71

the risk of measles importation, with a particular goal of enabling the Ministry to better inform travellers and understand high risk periods, we sought to use quantitative methods to evaluate the risk of measles importation.

For our initial analyses, we use arrivals data from New Zealand immigration ([www.immigration.govt.nz](http://www.immigration.govt.nz)) as a proxy for human movement to and from New Zealand. We collated country population size, measles incidence and measles vaccination cover from the WHO ([www.who.int/research/en/](http://www.who.int/research/en/)).

The preliminary analyses of 2012 data, the most complete and current year of data, suggest immigration (whether for work, pleasure, etc.) is dominated by Australia, United Kingdom, China, and the United States, as shown in Table 1. However, vaccination coverage is lowest and measles incidence highest in less developed nations (Table 3 and Table 2). Though the precise interactions between these different risk factors are unknown, the most simple, a product

of measles incidence in 2012 and immigration numbers in 2012, suggest that though immigration is lower from some Asian countries, travel from (and thus we presume to) some Asian countries also poses a high risk of measles importation to New Zealand. These data are shown in Table 4. The data for all the variables for each nation state and territories for 2012 are plotted in Figure 2, Figure 3, and Figure 4 and the risk map for measles incidence and immigration in Figure 5.

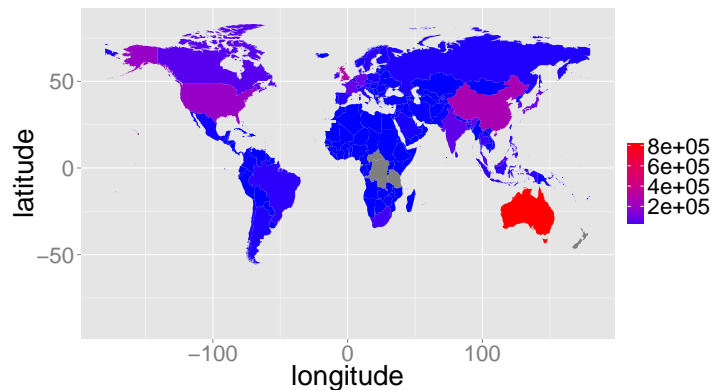

Figure 2: Immigration to New Zealand 2012

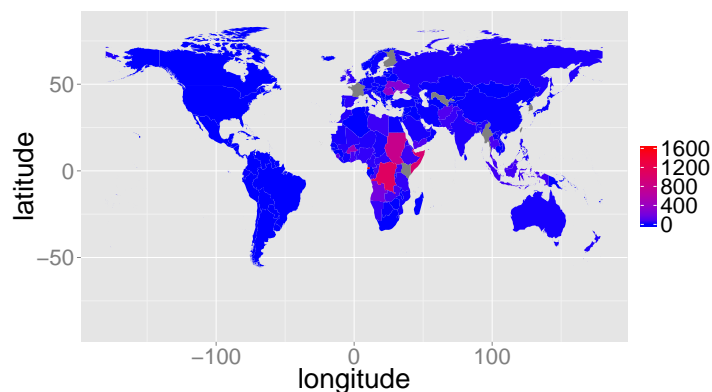

Figure 3: Measles incidence per million 2012

Though global incidence of measles is declining, in recent years that decline has slowed (Figure 6) and immigration rates to New Zealand have risen (Figure 7). This suggests that the risk of measles importation could increase, though further analyses are required to understand these interactions between these. Of note, however, is the clear seasonality in immigration (Figure 7). This seasonal-

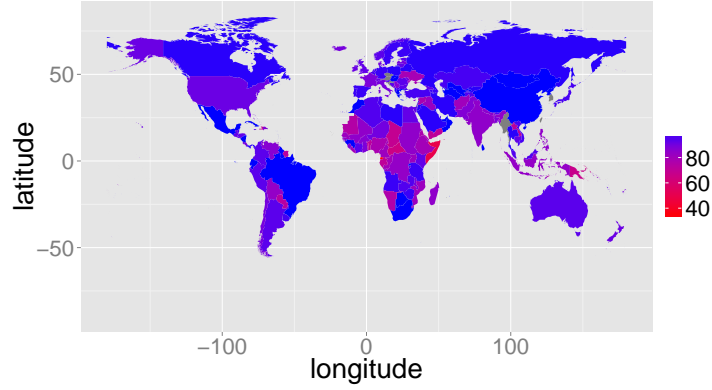

Figure 4: Measles vaccination cover (%) 2012

Figure 5: Risk map from measles incidence and immigration rates

ity suggests that there may be period of increased risk of measles importation, though again the interactions with seasonal measles transmission from the nations of origin or travel to will be an important factor in determining the risk of measles importation.

### 3.2 Risk analysis summary

- There is a continued, and perhaps increasing, risk of measles importation due to travel and endemic measles elsewhere in the world.
- There may be seasonal changes in risk of measles importation, though further analyses are needed.

Figure 6: Trend in global per capita measles incidence

### 3.3 Future risk analyses

We received the raw EpiSurv measles case data from The Institute of Environmental Science and Research Ltd (ESR) on 27 June 2014. Initial analyses of those data (not shown) suggest that we require denominator data to perform multivariate analyses to avoid confounding results due to a lack of independence among risk factors. Specifically for the multivariate analyses we wish to perform that detect interactions we require *Age \* Prioritized Ethnicity \* NZDep* data for New Zealand to see if the interactions among case covariates give us any additional information on risk from the univariate analyses already performed in the report reviewed above. These data only became available to us on 3 July 2014 after because ESR and NZ Statistics did not have those data and we had to obtain these from the University of Otago.

The following analyses are still in progress and aim to include them in later reports:

- Multivariate regression analyses to look for interactions between risk factors that may confound the univariate analyses.
- Update of the importation risk analyses using more than the 2012 data,

Figure 7: Trend in total immigrations into New Zealand

including modeling the trend in importations.

Additional data we believe would enable us and the Ministry to understand measles risk better is fine scale (lower than District Health Board (DHB)) immunization coverage data. Thus the data gap that we have that will hinder us providing fine scale risk maps are:

- A lack of meshblock level immunisation coverage data to allow targeted immunisation and understanding of risk at a fine scale level.
- The number of New Zealanders arriving from abroad each year.

We understand the National Immunisation Register (NIR) allows tracking of the vaccination status of children and this is very useful, but inclusion of these data at lower (e.g. *meshblock*) level would allow better understanding of risk of measles infection and resource allocation because they may allow targeted immunisation programmes.

## 4 Cost analyses

In this section we provide a review of the costs of measles from other locations and an analysis of the costs involved with this current measles outbreak.

Approximately 50 years ago, approximately 135 million cases and 7-8 million deaths were believed to occur in the world (Clements and Hussey, 2004). Thirty years later, it was estimated there were still approximately 45 million cases of measles offering annual, including 6 million measles-related fatalities. Wolfson et al. (2007) estimated that in 1999 measles was responsible for more than 30 million disability adjusted life years (DALYs) lost and 12 million in 2005. Similarly, the number of cases was reduced by more than 50% from 43 million in 1999 to approximately 20 million in 2005. They estimated approximately 7.5 million deaths from measles were avoided from 2000-05 due vaccination. The World Health Organization (WHO) estimated 158,000 deaths from approximately 355,000 measles cases in 2011 (WHO, 2013). In addition to the substantial losses occurring in measles-endemic countries, a significant impact is felt in heavily measles-vaccinated countries, which may be considered measles-free, due to contact with cases either in the country of origin or in the previously measles-free country.

The annual cost of treating and controlling measles in 11 industrialised countries was estimated to cost more than US\$ 150 million (Carabin et al., 2003). The estimated cost for a case ranged from US\$ 189-344 (Carabin et al., 2003); however, the average estimated cost of a typical hospital case ranges from US\$ 967-1,755 (Carabin et al., 2002). Stack et al (2011) estimated the economic benefits from cases averted due to measles vaccination. They estimated that the expanded vaccination from 2005 to 2015 in 72 of the world's poorest countries could result in nearly US\$ 10 billion of costs averted between 2011 and 2020. Ninety-nine percent of these averted costs were the result of lost productivity due to an estimated 360,000 measles-specific premature mortalities, with the remaining 1% associated with averted treatment costs and reduced caretaker productivity for the nearly 12 million measles cases avoided.

Italy has the highest reported annual cost of measles among industrialised countries (Carabin et al., 2003). In 2001, it reported losses related to measles of approximately US\$ 50 million. The economic impact of a large measles outbreak in Italy, 2002-03 examined the costs associated with 5,154 hospitalizations where measles was the main discharge diagnosis. The mean length of hospital stay was 5.2 days (median = 4 days and range = 1 to 303 days). The total cost of these hospitalizations amounted to 8.83 million (1 NZ\$ 2.0 in 2002-03), or approximately 1,700 per case. The average cost per non-complicated measles was 1,429, while the mean cost of a case with complicated measles was 2,721. The average daily cost of a hospital stay was 327.

An outbreak of measles occurred in Sydney, Australia, lasting nearly 2 months in 2011 and resulted in 26 confirmed cases (Flego et al., 2013). Seven (27%) of the cases required hospitalization for more than 1 day and 10 (38%) resulted in management within a hospital emergency department. During this outbreak, a total of 1,395 contacts were identified and managed by a public

health unit in western Sydney. The mean number of contacts per case was 54 (median = 28, maximum = 206). The estimated cost to the public health unit for contact management for the epidemic was in excess of A\$ 48,000, with 90% of this being associated with staff time.

Germany implemented a two-dose measles vaccination program in 1991 and has seen the benefits in recent years. In 2001 more than 6000 cases were reported in Germany but by 2004 this number fell to 122 (Wichmann et al., 2009). However, in 2005 more than 500 cases were reported by the middle of the year in two German states, with the vast majority (>95%) in non-vaccinated children (Siedler et al, 2006). An economic analysis was performed of the 614 measles cases reported in an 8-month period in Duisburg in the state of North Rhine-Wesphalia (NRW). In that study, they estimated the health-care provider costs to be approximately 229,000, or 373 per case. Approximately 78% of these costs were associated with the 95 (15.5%) of the cases that were hospitalized. The mean costs of the hospitalized patients was 1,877, including one patient with encephalitis at a cost of 35,623. In addition to the health-care provider costs, additional costs of 89,400 were incurred by the district public health office, the majority (85,000, 95.1%) for personnel, 2,300 (2.6%) for vaccination, and 2,100 (2.3%) for serologic testing. Therefore the combined direct costs of these 612 cases amounted to 318,400, or 520 per case. In addition, to determine the total impact, it would be necessary to include the indirect losses associated with lost production of cases and care givers.

Although measles was declared eliminated from the United States in 2000, it remains a concern due to the endemic nature of it around the world (Parker et al., 2006). Several studies have been conducted in the United States to assess the economic impact of recent measles outbreaks due to imported measles. Ortega-Sanchez et al. (2014) estimated the economic impact to public health departments in the US as the result of 16 outbreaks in 2011. The outbreaks lasted an average of 22 days and resulted in 107 confirmed cases; however, from these 107 cases, they estimated between approximately 8,900 and 17,500 contacts with confirmed cases, requiring between 42,600 and 83,100 personnel hours at a cost of between US\$ 2.7 and 5.3 million. Overall, it was estimated that each contact required 4.7 personnel hours at a cost of US\$ 298 per contact. Dayan et al. (2005) calculated the cost of containing a single case of measles that occurred in Iowa in 2004. They estimated that for the one week that the Iowa Department of Public Health (DPH) investigated the case, 2,525 hours were used to identify contacts, set up vaccination clinics, and institute and enforce quarantine orders for those who refused vaccination. In total, it was estimated the direct costs associated with three cases of measles was US\$ 142,452, or nearly US\$ 50,000 per case.

Parker et al. (2006) reported the impact of a large measles outbreak due to a non-autochthonous case in Indiana. A total of 34 cases, 94% of which were not vaccinated against measles were reported in the outbreak. Direct cost information was obtained from approximately 100 public health officers and infection-control officials needed to control the outbreak. Direct cost for those completing a survey showed the outbreak cost at least \$167,685, 83% of which

(\$139,023) was for wages, salaries and overhead. This amounted to a direct cost of \$4,932 per measles case. These costs did not include either patient care or indirect costs, which would have made the total and per case cost higher.

Coleman et al. (2012) estimated the direct medical and public health costs in response to a single case of refugee-imported case measles. Costs included labor, translation, benefits for public health workers. In addition, medical costs were incurred due to vaccination, immunoglobulin, testing for measles immunity, hospitalization, transportation and diagnosis. In total, 387 hours were associated with this single case, resulting in a cost of US\$ 11,881. In addition, per-contact costs amounted to US\$ 264. The cost of hospitalization for the 3-day stay by the index case was US\$ 931. Additional costs were associated with physician visits (US\$ 294), vaccine and immunoglobulin (US\$ 1,765), mileage (US\$ 205) and immunologic screening tests for the parents' exposed to measles (US\$ 240) for a total of US\$ 23,816. Economic analyses of measles control programs have shown them to be financially effective. In the Republic of Korea, the economics of alternative measles vaccination programs were compared. All of the alternatives were found to be economically efficient (benefit/cost ration (B/C) > 1.0), with the alternative using two doses of the MMR program, with a catch-up campaign for measles and rubella being the most favourable (B/C = 1.27). The purpose of the current study is to estimate the cost of the current measles outbreak in New Zealand. Using this information, we will then evaluate the economics of alternative measles control strategies in order to provide additional information to public health officials and decision makers.

## 4.1 Methods

Costs were evaluated as either direct or indirect. Direct costs included physician consultations, hospitalisations, drugs, vaccination, long-term care for chronic sequelae, special education costs. Direct costs can be divided into medical and non-medical (Saha and Gerdtham, 2013). Direct medical costs include costs for diagnosis, treatment, continuing care, rehabilitation and terminal care. Personnel time (investigation and emergency response), materials (phone calls, vaccine, personnel (cost, wages and fringe benefits), overhead costs, public information, and mileage are estimated when calculating direct medical costs. Direct non-medical costs include transportation to and from health care providers. Indirect costs are productivity losses for the case and/or health care provider, e.g. parent of a school child. Indirect costs included work loss for cases and caregivers. This could also include the economic value of premature life lost, costs associated with permanent disability, e.g. deafness and mental retardation. Commonly the human value approach (HVA) has been used to estimate economic impact of life. The HVA measures the potential future earnings of an individual and discounts it into a present value. Typically this is 3% but 5% has also been used in a sensitivity analysis, which is more compared to non-human life calculations and will tend to reduce the present value of the future earnings (saved by avoiding a case). Data for the current measles outbreak were obtained from the New Zealand Ministry of Health, from 2008 through June 2014. Data

included information on gender of the case, ethnicity and age of the case at discharge from hospital, days spent in the hospital, year of case, number of events, case weight and associated cost.

Cost of the Auckland Regional Public Health Service (ARPHS) for measles response were obtained from the Ministry of Health. Data, for the period January 1 - March 9, 2014, reported salaries for people involved with the measles outbreak management medical team. The costs were reported as direct, additional (above normal budgeting) costs required to enable the management of measles. It includes a breakdown by individual performing the work and whether it was during the normal work schedule (Monday to Friday, M-F) or weekends. Normal work was calculated as  $1.2 \times \text{full time equivalent (FTE)} \times \text{number of days worked}$ . Overtime was calculated as  $1.6 \times \text{FTE (M-F)}$  and  $2.0 \times \text{FTE (weekend)}$ . A full day was considered as 8 hours worked. Salary (hourly) rates were calculated for the following: public health nurse (PHN, \$36), public health assistant (PHA, \$22), data support (\$26), data support (temporary) (\$33), management and programme supervisors (\$40), incident management team (IMT), which had the following work titles: incident controller (\$96), administrator (\$24), planning and intel (\$40), logistics (\$36), communications (\$45), informatics (\$40), operations (\$40), and safety/security officer (SSO) (\$26). In addition, measles operations personnel were calculated at a daily rate of \$600 and operations partners and IMT controller partners at \$729.

Mean wages for New Zealand workers, by age and gender were obtained for the period, 2008-2013 from the New Zealand Income Survey (Statistics New Zealand, 2013). Measles cases were assumed to not work for a period of 5 days. Similarly, a care taker was assumed to not work for 5 days if the case were less than 20 years of age. In order to calculate the wage loss associated with the care taker, it was assumed that the person was a female between the ages of 35-39. Age and gender information for the 192 publicly funded hospital discharges with a measles primary diagnosis from 2008-2013 were matched to the New Zealand wage file to calculate lost wages due to measles.

A regression analysis was performed to test for significant associations between hospital cost and the following explanatory variables: case age at discharge, gender, length of stay (days) and year of case.

## 4.2 Results

Direct costs for measles management in New Zealand for the 10-week period, January 1 - March 9, 2014 are shown in Table 5. The reported direct medical costs do not appear to include hospital medical costs, which are reported separately in Table 6.

The total cost for the 192 publicly funded hospital discharges with a measles primary diagnosis was \$289,694 (Table 6). The mean cost per case was \$1,509. The mean cost per day of stay in the hospital was \$1,154.

From 16 December, 2013 through 19 June, 2014 there were 201 confirmed measles cases in New Zealand (note 14 of these occurred before Jan 2014, so 187 occurred from Jan 2013 - 19 June 2014). The number of cases by age group is

Table 5: Estimated costs (NZ\$) for measles management in New Zealand, January 1 - March 9, 2014 (see text for abbreviations)

Category	January	February	March	Total

Table 6: Number of cases, length of hospital day, cost, cost per case and cost per day for patients with measles as the primary diagnosis, 2008-2013

Year	Cases	Days	Cost	Per.case	Per.day
2008	3	1	3,038	1,013	3,038
2009	29	38	40,782	1,406	1,073
2010	5	5	6,701	1,340	1,340
2011	132	189	205,303	1,555	1,086
2012	19	12	28,540	1,502	2,378
2013	4	6	5,330	1,333	888
Total	192	251	289,694	1,509	1,154

Table 7: Frequency of measles cases and number and proportion admitted to hospital by age group, 16 December, 2013 - 19 June, 2014

Age	Cases	Admitted	Proportion
<15 months	21	10	0.47
15 months – 3 years	7	1	0.14
4 – 9 years	8	0	0.00
10 -1 19 years	132	12	0.09
>19 years	33	11	0.33
Total	201	34	0.17

shown in Table 7. Of these 201 cases, 34 (17%) were admitted to hospital with the highest proportion occurring in the youngest (< 15 months) and oldest (> 19 years) age groups, 0.47 and 0.33, respectively.

The majority (191/192) of the measles cases stayed in the hospital from 0 to 7 days, with the exception of a male patient, who was discharged in 2011 at age 57, after a stay of 19 days and a cost of \$8,213. Eighty-three of the cases stayed for 0 days and the remaining cases stayed a mean of 2.30 (median 2) days. The number of cases, length of hospital stay, cost, cost per case and cost per day for patients with measles as the primary diagnosis, by year and gender for 2008-2013 appear in Table 8. The cost for these 192 hospitalizations was \$289,964. Of the 292 cases, 87 were female and 105 were male. The number of days spent in the hospital was 251, making the mean daily cost of \$1,509. Of the 251 days, 114 were spent by females and 137 by males. The mean hospital stay per case was 1.31 and 1.30 days for females and males, respectively. The mean cost per case was \$1,573 and \$1,456 for females and males, respectively.

Regression analyses showed statistically significant associations between cost of hospitalization and three variables, length of hospitalization, case age and year of case, and a less strong association with case gender (Table 9). Results showed an increase of approximately \$358 per day of hospitalization, \$139 for a female case, and \$1 per year of case diagnosis. The cost was found to decrease by approximately \$5 per year of case age.

Wages lost due to measles were calculated based on the assumptions that 5 days of work were lost for each case; however, individuals between 0-15 years of age were not assumed to be employed and therefore did not suffer an income loss. If the case were < 20 years of age, it was assumed there was an income loss of 5 days for the care giver, in addition to the wage loss of the case if 15-19 years of age. Total wage lost for the 192 cases and care givers was estimated to be \$166,638. This consisted of \$90,620 for the cases and \$76,018 for the care giver, but did not include wage losses for cases <15 years of age.

This final figure brings an approximate estimate of \$786,479 for the current 2014 outbreak, which is comprised of earnings lost, case management and hospitalisation costs.

Table 8: Number of cases, length of hospital stay, cost, cost per case and cost per day for patients with measles as the primary diagnosis, by year and gender, 2008-2013

Year	Gender	Cost	Cases	Days	Per.case
2008	F	714	1	0	714
	M	2,324	2	1	1,162
	Total	3,038	3	1	1,013
2009	F	11,953	7	15	1,708
	M	28,830	22	23	1,310
	Total	40,782	29	38	1,406
2010	F	5,884	4	5	1,471
	M	817	1	0	817
	Total	6,701	5	5	1,340
2011	F	103,460	66	86	1,568
	M	101,842	66	103	1,543
	Total	205,303	132	189	1,555
2012	F	13,054	8	6	1,632
	M	15,486	11	6	1,408
	Total	28,540	19	12	1,502
2013	F	1,800	1	2	1,800
	M	3,530	3	4	1,177
	Total	5,330	4	6	1,333
Total		289,694	192	251	1,509

Table 9: Regression results ( $R^2$  adj = 0.9, p-value <0.001) for measles hospitalization cost based on length of stay (days), gender, case age and year of case (n=192) in New Zealand, 2008 - 2013

Variable	Coefficient	P.value
Length of stay (days)	357.71	<0.001
Gender (0 = F, 1 = M)	-138.55	0.084
Case age (years)	-5.23	0.032
Year of case	0.60	<0.001

### 4.3 Cost analysis discussion

The results presented here are based on available data. While some of the data are complete and detailed, this is not true of all the data. In order to perform an accurate analysis of the current measles outbreak in New Zealand, more complete data are needed. For instance, age, gender, ethnicity, year of discharge, length of stay and estimated cost data are available for cases reported by publicly funded hospitals. In addition to this information, similar data would be needed for cases occurring outside the period 2011-2013 at publicly funded hospitals. Similar data would be needed for non-publicly funded hospitals, e.g. private clinics. Detailed measles outbreak management costs were provided for the period of January 1 - March 9, 2014. Similar data are needed for the period preceding 2014. If detailed data, such as that provided for early 2014, aggregated data would be acceptable. However, it is unrealistic to assume that these costs would be linearly related with the number of measles cases, making it difficult to extrapolate these costs outside the reported period for 2014. As other studies have demonstrated, direct costs required to manage measles are not linear.

In other outbreaks, the average cost per measles case was estimated to be US\$ 254, US\$ 276, and US\$ 307 for Canada, the Netherlands, and the UK, respectively (Carabin, et al., 2002). This and other findings will be compared and contrasted with New Zealand costs, once more complete New Zealand data are made available. The containment of a single case (also 2 secondary cases) of measles in 2004 in Iowa, USA was estimated to cost US\$ 142,542. In this outbreak, more than 2500 hours of personnel time were needed to investigate and respond to the outbreak (Dayan et al., 2005). They estimated direct costs per case to be less than US\$ 500. The annual cost for long-term care of people with moderate or severe mental retardation over a period of 50 years is estimated at US\$ 31,059 and US\$ 78,448, respectively (Prouty and Lakin, 2000). In 2000 expenditures for care in large state mental retardation/developmental disabilities (MR/DD) facilities continued to increase and reached a national annual average of US\$ 113,864 per person. In 2000 the average annual expenditures for care in large state MR/DD facilities were \$ 113,864. The cost of a case of measles was estimated to range from \$ 71 (no complications and no hospitalization) to \$ 29,556 (encephalitis and hospitalization for 8.7 days). They estimated the annual cost of measles in the US with its vaccination program to be \$1,234,083 (52.5% direct cost and 47.5% indirect cost) (Zhou et al., 2004).

### 4.4 Cost analysis summary

- Our initial estimates suggest the ongoing 2014 measles outbreak has cost New Zealand over \$  $\frac{3}{4}$  million.

### 4.5 Future cost-benefit analyses

Using the results above we aim to:

- Estimate the costs for targeted vaccination, based either on the univariate analyses presented to date in the *Progress Towards Measles Elimination in New Zealand - Final* report or adjusted if any additional risk groups are identified in the multivariate analyses or modeling.

We also require additional clarifications of the data, regarding what hospital costs refer to, such as if a hospital day were 0 does that mean the case stayed in the hospital but not overnight? Or, does it mean the case stayed for less than 24 hours? Once more complete data are available, comparisons of these results will be made to other published studies, discussed above.

## 5 Modeling measles epidemics

A previously-published model of the dynamics of measles infections in New Zealand has been used to evaluate the vaccination strategy in New Zealand of MMR1 at 15 months and MMR2 before 5 years. The results show that achieving coverage of >90% at both vaccination opportunities is necessary if future epidemics of measles are to be prevented.

The original mathematical model for the dynamics of measles in New Zealand prepared in 1996 (Tobias Roberts 1998) successfully predicted the 1997 epidemic, which was curtailed by a mass vaccination campaign (Mansoor et al 1998; Roberts Tobias 2000). Subsequent extension of this work in 1998 showed that the then current schedule of MMR1 at 15 months and MMR2 at 11 years was insufficient to prevent further epidemics. The model developed by Roberts Tobias (2000) supported the change in the immunisation schedule that took effect in January 2001, at which time MMR2 was changed from delivery at 11 years to delivery before the age of five. The schedule was changed in 2000 with MMR2 now being administered before 5 years (Anon. 2002a) and later analyses suggested high levels of vaccination coverage (but less than 95%) could eliminate measles, but emphasized that it is necessary to maintaining high coverage rates in order to prevent future epidemics.

These results were in line with those obtained by other authors, for example: Babad et al (1995) advocated a two-dose schedule for England and Wales, with the second vaccination given at age four; and Gay et al (1998) recommended a second vaccination at either 18 months or five years, to complement the first vaccination at 12 months in Canada. In addition, Agur et al (1993) found that vaccinating 85% of susceptible children aged one to seven years at five-yearly intervals would prevent epidemics in Israel. These authors all agree that two vaccinations at no less than five years apart are necessary to prevent measles epidemics. A different approach was taken by Wallinga et al (2001). These authors took existing policies in eight European countries and estimated the coverage rates required to reduce  $R_v$  below one. They found that results depended on the age at delivery, but no strategy succeeded if coverage rates were below approximately 87%.

A variety of similar models for measles vaccination strategies have been developed by other authors for various regions (Agur et al 1993; Babad et al

1995; Edmunds et al 2000; Gay et al 1998; Wallinga et al 2001) based on sets of nonlinear differential equations (ODE), and the conclusions reached have been similar. The differences in the models have been in the details of the representation of the infectious period, and in the ways in which the age and contact structures of the population have been specified.

It is difficult to estimate the proportion of the school-age population that have been effectively immunised, but this is continuously being diluted by children who are not immunised. While analyses suggest that 85% coverage at MMR1 and MMR2 could be sufficient to prevent future measles epidemics, Glass et al (2004) in the Netherlands showed that high overall levels of measles vaccination can obscure pockets of poor coverage, resulting in localised regions with increased risk of infection.

The quantity that determines whether an epidemic will occur is the basic reproduction number of the infection,  $R_0$ . This is defined as the expected number of secondary infections that would arise from a single primary infection introduced into a fully susceptible population (Anderson May 1991; Diekmann Heesterbeek 2000). If  $R_0 > 1$  an epidemic will occur following an introduction of infection. The best estimate we had for measles in New Zealand was  $R_0 = 12.8 - 12.5$  (Roberts, see results section). The basic reproduction number of the infection under vaccination,  $R_v$ , is the expected number of secondary infections that would arise from a single primary infection introduced into a vaccinated population at equilibrium and is a robust indicator of the performance of a vaccination schedule. If  $R_v < 1$  epidemics are prevented. The case reproduction number of the infection at time  $t$ ,  $R_t$ , is the expected number of secondary infections that arise from a single infection at a particular time and depends on the number in the population who are susceptible.

To understand the level of immunity in the population, how likely an outbreak was of becoming endemic, we estimated  $R_v$  from all the outbreaks since 2009. To do this we estimated  $R_t$ , following an adaptation of the methods in [REF], and used these to estimate the  $R_v$  of measles in the recent outbreaks, which helps understand the transmission dynamics of measles in the partially immune population.

To estimate  $R_t$  we were required to compute the generation time for measles. We used a lognormal distribution with mean 12.0 and standard deviation (s.d.) 3.5 from We then estimated  $R_t$  using the methods adapted from [REF] from the incidence data for each outbreak. We defined outbreaks in the dataset given their temporal and geographic correlations (Figure 8). The outbreaks we used in our analyses are shown in Figure 9.

The estimated  $R_v$  for each outbreak is shown in (Figure 10). The probability density of the  $R_v$  estimates for each outbreak all include one. Of particular note is the ongoing outbreak, which has an  $R_v$  well above one and thus we may expect this outbreak to persist if conditions remain the same.

These analyses also imply that the regular (approximately yearly) importation of measles is an ongoing process. Given the risk of importation of measles, as highlighted in the *risk analysis* section is likely to continue these analyses suggest substantial efforts are required to maintain the level of immunisation

Figure 8: Measles cases by district health board (DHB) from 2009 to 2014

Figure 9: Measles data classified as outbreaks for reproductive number of the infection ( $R_v$ ) estimation

Figure 10: Estimates of  $R_v$  ( $R_0$ ) for the outbreaks each year, as classified in Figure 9 (page 21)

to high enough levels that measles does not become endemic. The measles outbreak in 2011-2012 had an  $R_v$  of just greater than one, and yet it persisted for over 12 months. This implies that the current outbreak may persist within the population for a substantial period, given it's  $R_v$  is approximately twice that of the 2011-2012 outbreak. A caveat to this and other  $R_v$  estimates is that the 2013-2014 may include some sporadic cases and thus the true basic reproductive numbers may be lower than estimated. However, sub-clinical and underreporting may lower the estimate. The relative contributions of both to our estimates are currently unknown.

## 5.1 Summary of modeling

- Regular introductions of measles pose an ongoing threat to New Zealand's efforts to eliminate measles (also see section [X]).
- The reproduction number for measles in a partially immune population is often close to one, suggesting increased population level immunity is required to prevent this measles persisting.
- The reproduction number for measles in the current outbreak is well over one, suggesting that this outbreak has the potential to become endemic.

## 6 Future modeling analyses

Future modeling analyses we aim to perform are:

- An update of previous ODE models of measles outbreak risk in the overall population according the differing vaccine coverage scenarios.
- Model measles outbreaks with differing scenarios of measles importation into various population groups based on current introduction rates.

## 7 Summary of key findings

- New Zealand is at risk of frequent measles importation due to travel and endemic measles elsewhere in the globe.
- The cost of the current measles outbreak is estimated to be at least \$ $\frac{3}{4}$  million.
- Analyses of outbreak data suggest that measles  $R_v$  values often include 1 and in this year, 2014, well above one. This analyses suggest improved vaccination is a requisite to prevent measles becoming endemic again.

## 8 Acknowledgments

The authors wish to thank Tomasz Kiedrzyński, Lisa Oakley and Nic Aagaard from the Ministry of Health, Ruth Pirie and colleagues from ESR, and June Atkinson from University of Otago for help in obtaining the appropriate materials for analyses.
